- **Visual Reconstruction:** Recover a model of a 3D scene from multiple images.
- **Scene Model:** Collection of isolated 3D features, e.g., points, lines, etc.
- **Bundle Adjustment:** Problem of refining a visual reconstruction model to produce **jointly optimal** 3D structure and viewing parameter (camera pose/calibration) estimates.
- **jointly:** Solution is simultaneously optimal with respect to both structure and camera variations.
- **optimal:** Parameter estimates are found by minimizing some cost function that quantifies the model fitting error.
- **Bundle** in the name refers to the bundles of light rays leaving each 3D feature and converging on each camera center.

Why use Bundle Adjustment

Reasons for using Bundle Adjustment over alternative adjustment methods

- **Flexibility:** handles very wide variety of sources of information (like priors).
- **Accuracy:** provide precise and easy to interpret results.
- **Efficiency:** Use rapidly convergent numerical methods and make good use of sparsity.

Notations (abstract)

Bundle Adjustment

Ariyan Zarei

Bundle Adjustment Problem Formulation

Parameter Estimation Methods

Numerical Optimization

References

The End

- State Vector X : large vector of all parameters
 - 3D locations of the keypoints
 - Camera parameters
- \underline{Z} : observations, measured image features.
- $Z = Z(X)$: predicted values corresponding to the observation from parameters X .
- $\Delta Z(X) = \underline{Z} - Z(X)$: residual prediction error.
- $f(X) = f(predz(X))$: cost function.
- $g = \frac{df}{dX}$: Gradient of the cost function.
- $H = \frac{d^2f}{dX^2}$: Hessian of the cost function.
- $J = \frac{dZ}{dX}$: Jacobian of the observation w.r.t. states.

The End

$$f(x) = \frac{1}{2} \sum_i \Delta Z_i(X)^\top W_i \Delta Z_i(X)$$

$$\Delta Z_i(X) = \underline{Z}_i - Z_i(X)$$

- $Z_i = Z_i(X)$: predicted value of the feature i corresponding to the observation from parameters X .
- \underline{Z}_i : observed value of feature i .
- W_i : symmetric positive definite weights.
- Minimizes the weighted sum of squared error.
- Equivalent: observations perturbed by Gaussian noise with mean zero and covariance W_i^{-1} .

Robustified Least Squares

- Nonlinear Least Squares are highly sensitive to outliers. We want to damper the effects of outliers.
- Example of outliers: incorrect SIFT matchings
- RANSAC
- observations are considered independent (independence groups)

- cost functions can have any form. One natural family of cost functions are **radial distributions**:

$$f_i(x) = \frac{1}{2} \rho_i(\Delta Z_i(X)^\top W_i \Delta Z_i(X)^2)$$

- ρ_i can be any increasing function with $\rho_i(0) = 0$ and $\frac{d}{ds} \rho_i(0) = 1$.
- Model the error distribution as a Gaussian central peak plus a uniform background of outliers.

$$f(x) = - \sum_i \log(e^{-\frac{1}{2}(\Delta Z_i(X)^\top W_i \Delta Z_i(X))^2} + \epsilon)$$

$$f(x) = - \sum_i \sum_p \log(e^{-\frac{1}{2}(\Delta x_{ip}^\top W_{ip} \Delta x_{ip})^2} + \epsilon)$$

- $\Delta x_{ip} = \underline{x}_{ip} - x_{ip}$: difference of the observed and predicted feature locations.
- ϵ parametrizes the frequency of outliers.

The End

- Intensity-based Models: observables are intensities (of the patches of images)
- Implicit Models: Relations between predictions and parameters are not explicit.
 - We used to have $Z = Z(X)$ in which Z is expressed explicitly in terms of the parameters.
 - Here we have $h(X, Z) = 0$.
 - two approaches to handle implicit models
 - Nuisance parameters: convert to a constrained optimization by adding Z as Nuisance parameters. Minimize $f(\underline{Z} - Z)$ over (X, Z) subject to $h(X, Z) = 0$.
 - Reduction: Consider $h(X, \underline{Z})$ instead of \underline{Z}

The End

- Minimize cost function $f(X)$ starting from some approximations for X .
- Not possible to minimize in closed form.
- Take steps in the directions of reducing cost function locally and possibly reducing it globally.
- Take advantage of Taylor series.

Second Order Methods

■ Taylor Series

$$f(x) \approx f(a) + \frac{f'(a)}{1!}(x - a) + \frac{f''(a)}{2!}(x - a)^2 + \dots$$

Second Order Methods

- Quadratic Taylor Approximation of the cost function

$$f(X + \delta X) \approx f(X) + g^\top \delta X + \frac{1}{2} \delta X^\top H \delta X$$

- This is a local model with a global optimum.
- We proceed by taking the Newton's step:

$$\delta X = -H^{-1}g$$

Remarks:

- Needs Step Control
- Computation Complexity of each step is $O(n^3)$.
- Calculating H is not easy.
- Starting point is very important. Convergence becomes difficult when starting point is far from global minimum.

Step Control

- Newton's method might fail
 - Converge to saddle point
 - Occasionally true cost might not decrease when approximate cost decreases
- Descent Direction
 - A direction with a non-negligible component down the local cost gradient.
 - Take a combination of Newton's step and gradient direction

$$(H + \lambda W)\delta X = -g$$

- λ controls the combination and W is a PSD weight matrix.
- Trust Region Methods: Choose maximum size of the step dynamically
- Levenberg-Marquardt Methods: λ increases and decreases based on the whether the approximation gets better or worse.

The End

Gauss-Newton

- Jacobian of the predictions w.r.t. the parameters

$$J = \frac{dZ}{dX} = \begin{bmatrix} \frac{dZ_1}{dX_1} & \frac{dZ_1}{dX_2} & \cdots & \frac{dZ_1}{dX_n} \\ \frac{dZ_2}{dX_1} & \frac{dZ_2}{dX_2} & \cdots & \frac{dZ_2}{dX_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{dZ_m}{dX_1} & \frac{dZ_m}{dX_2} & \cdots & \frac{dZ_m}{dX_n} \end{bmatrix}$$

- Gradient and Hessian can be written in terms of Jacobian

$$g = \frac{df}{dX} = \Delta Z^T W J$$

$$H = \frac{d^2 f}{dX^2} = J^T W J + \sum_i \left(\Delta Z^T W \right)_i \frac{d^2 Z_i}{dX^2}$$

$$g = \frac{df}{dX} = \Delta Z^T W J$$

$$H = \frac{d^2 f}{dX^2} = J^T W J + \sum_i \left(\Delta Z^T W \right)_i \frac{d^2 Z_i}{dX^2}$$

- We can drop $\sum_i \left(\Delta Z^T W \right)_i \frac{d^2 Z_i}{dX^2}$ if either
 - Prediction Error ΔZ is small
 - Model is nearly linear or $\frac{d^2 Z_i}{dX^2} \approx 0$
- Results would be Gauss-Newton approximation

$$\left(J^T W J \right) \delta X = -J^T W \Delta Z$$

References

The End

- Gauss-Newton is an approximation of the SSE

$$\left(J^T W J\right) \delta X = -J^T W \Delta Z$$

- Very common specially in [bundle] adjustment methods.
- Disadvantages
 - Sometimes discarded terms are not negligible
 - Very sensitive to saddle point

Robustified Gauss-Newton

- Recall Least Squares and Robustified Least Squares

$$f(X) = \frac{1}{2} \sum_i \Delta Z_i(X)^\top W_i \Delta Z_i(X)$$

$$f_i(X) = \frac{1}{2} \rho_i (\Delta Z_i(X)^\top W_i \Delta Z_i(X))^2$$

- In robustified Least Squares we introduce nonlinearity at the level of individual features.
- Disadvantages of Gauss-Newton does not extend to the robust cost functions

$$g_i = \rho_i' J_i^\top W_i \Delta Z_i$$

$$H_i = J_i^\top (\rho_i' W_i + 2\rho_i'' (W_i \Delta Z_i)(W_i \Delta Z_i)^\top) J_i$$
